### SUMMARY

- 1. This task included the setup, instrumentation, testing and data compilation for a single generator 270 volt DC (direct current) aircraft electric power system.
- 2. The generator system was interconnected, instrumentation was completed, and operational tests were conducted. Several deficiencies were observed:
  - (a) The generator coolant reservoir was too small to contain the coolant expansion at operating temperatures. This caused coolant loss through the reservoir relief valve. An external expansion tank was added to correct this problem.
  - (b) A water cooled heat exchanger did not provide controllable generator coolant temperature. An air cooled exchanger was substituted in the test setup with improved results.
  - (c) The generator drive stand speed was limited to 10,500 RPM (revolutions per minute). Repair and adjustment of drive electronics was required to obtain speeds over the range 9,000 to 18,000 RPM.
- 3. Generator voltage regulation tests over the rated speed and load range disclosed:
  - (a) 270 volt DC output voltage was maintained over rated speed and load with momentary application and removal of rated loads.
  - (b) Voltage transients exceed specified limits with load application and removal.
  - (c) Voltage transient recovery time is within allowable limits for rated load application and removal.
  - (d) High ripple voltage developed during tests at 14,000 RPM and remained high during the balance of the voltage regulation tests. The ripple voltage exceeded specified limits - 24 volt P/P (peak to peak). The generator high ripple protection did not trip as required. However, it did trip once during the 17,500 RPM tests and reset when the control switch was cycled.

- 4. Coolant loss was a continuing operational problem. The addition of an expansion tank helped, but it did not solve the problem. During temperature stability tests, coolant was lost. There was no visible dripping but there was a vapor cloud over the generator. On July 1, coolant started to drip from the front and rear generator flanges.
- 5. On July 9, after approximately 100 hours of generator operation, the generator developed a ground fault. There was a blow out, with fire, from the rear manifold. The fire extinguished. Heavy vapor then enveloped the generator and coolant was observed flowing at the front and rear flanges. Fire engulfed the generator and was put out with carbon dioxide extinguishers. The fire was extinguished approximately one minute after symptoms of the ground fault were observed on video tape.
- 6. Subsequent closed cup flash point tests of samples of Coolanol 25 which was drained from the generator coolant system showed that the Coolanol 25 flash point had degraded to room temperature (less than 78°F). The manufacturers' technical bulletin specifies flash point (minimum) 325°F.

### INTRODUCTION

## 1. Background

The Navy is developing an advanced electric power system for future military aircraft. The system consists of the 270 volt DC generator, regulator, protective and distribution system components necessary to implement a complete aircraft system.

The development of the system components is presently under contract to various avionic and airframe contractors. As each component type is delivered, it is necessary that it be subjected to various performance tests to determine if the essential performance requirements and design goals have been met. This information will be used to establish state-of-art tradeoff alternatives for component development and system performance criteria.

## 2. Scope

This task includes the setup, instrumentation, testing and data compilation for a single generator 270 volt DC electric power system.

# 3. Task One Effort

This first phase test consisted of completing a partially assembled test setup, conducting preliminary operational tests, and initiating generator voltage regulation tests over the rated speed and load range.

## TEST SETUP

- 1. A wiring diagram of the 270 volt DC system interconnection and instrumentation is shown on Figure 1 (Wiring Diagram, 270 VDC Generator Lab Test, NADC Drawing No. TE22082).
- 2. Additional instrumentation, not shown on Figure 1, consisted of thermocouple temperature monitoring of coolant temperature into the generator, coolant temperature out of the generator, and one generator bearing temperature. The generator had four thermocouples, but the only one operative was the one from the top of the generator rear manifold cover.
- 3. Closed circuit television camera monitoring and recording was also provided.

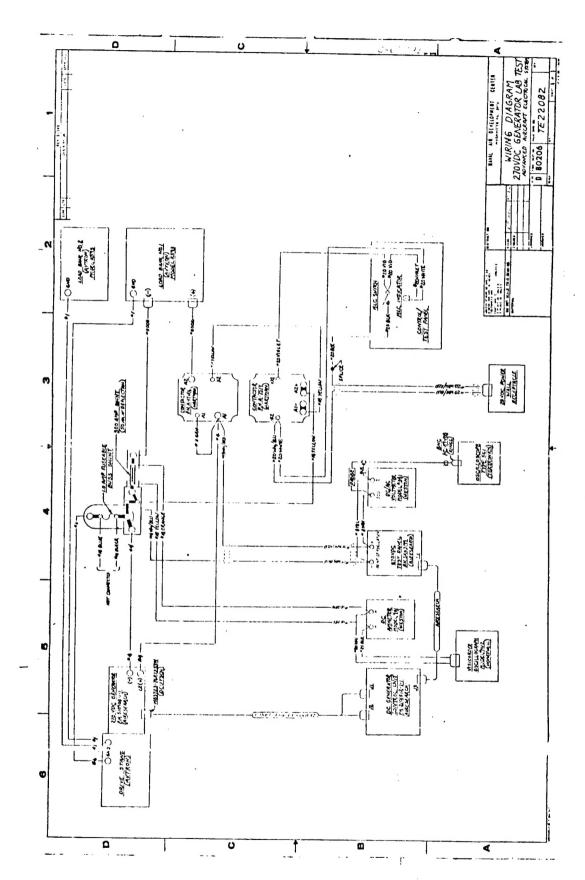

Figure 1

### OPERATIONAL TESTS

- 1. Prior to start of voltage regulation electrical test, operational tests of the generator were conducted to obtain some baseline data. It was established from discussions at NAVAIRDEVCEN that the maximum coolant temperature should be  $80^{\circ}$ C at the output of the heat exchanger (the input to the generator) with the generator under full load. Test Data Sheet #1 shows the results of tests wherein waterflow through a heat exchanger was adjusted to establish a maximum temperature of  $80^{\circ}$ C under full load.
- 2. The initial test disclosed an operating deficiency wherein the generator coolant system, including the reservoir, could not contain the coolant as it expanded from operational temperature rise. As a result, an expansion tank was added to test setup. Test Data Sheet #2 presents test results with the expansion tank in the setup. An additional operational problem appeared; coolant was lost during operational test although there were no visible signs of loss such as dripping coolant. However, a heavy vapor cloud was visible over the generator during tests.
- 3. Test Data Sheet #3 presents the data from a test conducted to determine the transient amplitude variations in the 270 volt DC level as the generator control panel three-position switch (OFF-TEST-ON) is switched from OFF to TEST to ON. Transients were recorded on the visicorder (Figure 1) using a fluid damped galvonometer, Type M3300, and matching network.
- 4. Test Data Sheet #4 presents the data from a test conducted to monitor generator coolant and bearing temperature rise under no load using the water cooled heat exchanger with the water flow set as was required to maintain coolant "in" at 80°C under full load. Since coolant exceeded the 80°C limit with

the exchanger water flow set as it had been to maintain  $80^{\circ}\text{C}$  with full load, it was concluded that the water cooled exchanger did not provide a controlled/stable temperature base line as required for generator tests. The water cooled exchanger was replaced by an air cooled exchanger with improved results.

### VOLTAGE REGULATION

- Test Data Sheet #5 presents data on a voltage regulation test.
   During this test we observed the first sign of coolant
   leakage. Coolant was found dripping from both the front and
   rear generator flanges and voltage transients were observed
   which exceed the contract referenced specification.
- 2. Test Data Sheet #6 presents generator RPM, voltage, coolant temperature "in", bearing temperature, and coolant flow during voltage regulation tests. Data is given under no It was at the completion of these tests that a 100% load was applied to the generator at 18,000 RPM. The purpose was to observe performance, temperature rise, stability, etc., under continuous load at 18,000 RPM for comparison with test results at 9,000 RPM. Shortly after application of the 100% load, a ground fault occurred. A blow-out was observed in the vicinity of the rear manifold, which ignited and then extinguished. A heavy vapor cloud was expelled by the generator and coolant was then observed flowing heavily from the front and rear flanges. Fire then engulfed the generator and was put out by carbon dioxide extinguishers approximately one minute after symptoms of the ground fault were observed. The sequence of events was recorded on video tape.
- 3. Test Data Sheet #7 (6 pages) presents results of tests at speeds from 9,000 to 18,000 RPM with momentary loads of 0 to 25%, 0 to 50%, 0 to 75%, and 0 to 100% applied and removed. At a speed of 14,000 RPM a high ripple voltage developed. Since it was above fault limits, 24V P/P for 200 ms, the generator voltage should have, but did not, cut off. Had this fault been observed, as a results of continual voltage cut off, it would have terminated tests and possibly prevented subsequent loss of the generator from the ground fault fire. Test data shows voltage transients in excess of specified limits with recovery time within allowable limits.

## CONCLUSIONS

- 1. The generator control unit failed to shut down the generator under high ripple voltage. There is a malfunction in the "Fault" circuitry.
- Coolanol 25 flash point changed after use in the generator cooling system; it became flammable at room temperature. Therefore, it is not suitable for aircraft generator coolant application.

### RECOMMENDATIONS

- Investigate high ripple fault circuitry to determine cause of malfunction.
- 2. Use Aircraft Turbo Shaft Engine Lube Oil (MIL-L-23699) as coolant in subsequent AiResearch 270 volt DC generators.
- 3. Return the failed generator to AiResearch for failure analysis, repair, and refurbish if practical.
